ABSTRACT: Two cases of haplosporidian infection occurred during 1993 in Pacific oysters *Crassostrea gigas* from the French Atlantic coast. The localization and ultrastructure of the plasmodia are described. *In situ* hybridization of infected tissue sections was conducted with DNA probes for oyster-infecting haplosporidians. The *Haplosporidium nelsoni*-specific DNA probe MSX1347 hybridized with the *C. gigas* parasite, and the *H. costale*-specific probe SSO1318 did not hybridize. Total genomic DNA was extracted from the infected tissue sections for polymerase chain reaction (PCR) amplification of the haplosporidian. PCR amplifications with *H. nelsoni*-specific primers and with 'universal' actin primers did not yield the expected products of 573 and 700 bp, respectively. A series of primers was designed to amplify short regions of small subunit ribosomal DNA (SSU rDNA) from most haplosporidians. The primers encompass a highly variable region of the SSU rDNA and did not amplify oyster DNA. PCR amplification of the infected *C. gigas* genomic DNA with these primers yielded the expected-sized product from the primer pair targeting the shortest region (94 bp). This PCR product was sequenced and it was identical to the corresponding SSU rDNA region of *H. nelsoni*.

INTRODUCTION

Haplosporidian parasites can infect several species of oysters. *Haplosporidium nelsoni* and *H. costale* cause extensive mortalities of the eastern oyster *Crassostrea virginica* on the east coast of the United States (Andrews 1966). Haplosporidian parasites also occur in European flat oysters *Ostrea edulis* (Van Banning 1977, Pichot et al. 1979, Cahour et al. 1980, Vivares et al. 1982, Bachère & Grizel 1983), Olympia oysters *O. lurida* (Mix & Sprague 1974), pearl oysters *Pinctada maxima* (Hine & Thorne 1998), and Pacific oysters *C. gigas* (Rosenfield et al. 1966, Katkansky & Warner 1970, Kern 1976, Comps & Pichot 1991, Friedman et al. 1991, Friedman 1996, Burreson et al. 2000). For these affected bivalve species, there is no evidence that the

haplosporidian parasites are responsible for significant mortality similar to those reported among eastern oysters *C. virginica*; however, Katkansky & Warner (1970) described a heavy haplosporidian infection in the connective tissues of a moribund Pacific oyster.

Haplosporidian parasites have been detected in Pacific oysters from different parts of the world, including Korea (Kern 1976), Taiwan (Rosenfield et al. 1966), Japan (Friedman et al. 1991, Friedman 1996), California, USA (Friedman 1996), and France (Comps & Pichot 1991), during routine histological examination for bivalve parasites. In this study, the discovery of haplosporidian plasmodial stages is reported in juvenile Pacific oysters from the French Atlantic coast during epizootiological surveys for bivalve pathogens. The lack of spores in infected oysters prohibited positive identification by morphological criteria; therefore, DNA-based diagnostics were used to identify the haplosporidian as *Haplosporidium nelsoni*.

MATERIALS AND METHODS

Source of specimens. 617 adult and 174 juvenile cultured Pacific oysters *Crassostrea gigas* were collected for routine histological surveys from different locations along the French Atlantic coast between January 1993 and October 1993.

Light microscopy. Oysters were examined for condition and gross signs of disease. After individuals were removed from the shell, they were sagittally sectioned, then half was placed in Davidson's fixative and the other half in Carson's fixative. Samples fixed in Davidson's fixative were dehydrated through an ascending ethanol series, cleared in xylene and infiltrated in paraffin in a tissue processor. Following these steps, samples were embedded in paraffin, sectioned at 3 or 4 μm thickness, stained by hematoxylin and eosin (H&E) and carefully checked for lesions and parasites.

Electron microscopy. Pieces of gill and digestive gland tissue stored in Carson's fixative were rinsed for 48 h in 0.2 M cacodylate buffer, fixed in 2.5% glutaraldehyde in 0.2 M cacodylate buffer at pH 7.2 and post-fixed in 1% osmium tetroxide in the same buffer. Specimens were dehydrated in an ascending ethanol series, cleared in propylene oxide and embedded in Epon resin. Blocks were cut on a LKB ultramicrotome. One μm thick sections for light microscopy were stained in 2.5% toluidine blue in 1% aqueous sodium borate solution. Ultra thin sections were collected on copper grids and double stained with uranyl acetate and lead citrate (Reynolds 1963) and observed in a JEOL JEM 1200 EX transmission electron microscope at 60 kV.

In situ hybridization. *In situ* hybridization was performed on Davidson's fixed, paraffin-embedded tissue of the oyster collected at Morlaix using 5 ng μl^{-1} of the *Haplosporidium costale*-specific DNA probe SSO1318 or the *H. nelsoni*-specific DNA probe MSX1347, as described elsewhere (Stokes & Burrenson 1995). These probes, which target one of the variable regions of the small subunit ribosomal RNA (SSU rRNA) gene are sensitive and specific for the target organisms (Stokes & Burrenson 1995, 1999). Positive control *in situ* hybridizations consisted of tissue sections of *Crassostrea virginica* infected with *H. costale*, collected from Burton Bay, on the Atlantic coast of Virginia, in May 1984 and *C. virginica* infected with *H. nelsoni*, collected from York River, a tributary of the lower Chesapeake Bay, in Virginia in November 1995. Negative controls contained no probe in the hybridization solution.

Polymerase chain reaction (PCR). DNA was isolated from tissue sections of the Morlaix oyster by 3 different methods, as previously described (Wright & Manos 1990, Vachot & Monnerot 1996, Shedlock et al. 1997). The genomic DNA isolated from each of these methods was subjected to PCR amplification using *Haplospo-*

ridium nelsoni-specific primers MSX-A' and MSX-B (Table 1). PCR reaction mixtures contained reaction buffer (10 mM Tris, pH 8.3; 50 mM KCl; 1.5 mM MgCl₂; 10 $\mu\text{g ml}^{-1}$ gelatin), 400 $\mu\text{g ml}^{-1}$ bovine serum albumin, 25 pmol of each primer, 200 μM each of dATP, dCTP, dGTP, dTTP, 0.6 units AmpliTaq DNA polymerase (Perkin-Elmer), and template DNA in a total volume of 25 μl . The MSX-A' + B reaction mixtures were cycled in a GeneAmp PCR System 9600 thermal cycler (Perkin-Elmer) 35 times at 94°C for 30 s, 59°C for 30 s, and 72°C for 1.5 min with final extension at 72°C for 5 min. Genomic DNA was tested for amplifiability using 'universal' eukaryotic actin gene primers 480 and 483 designed by G. Warr (Medical University of South Carolina) and M. Wilson (Mississippi State Medical Center). Amplification of oyster genomic DNA with these primers yields an expected product of about 700 bp. The actin PCR reaction mixtures were prepared and cycled as above, except the annealing temperature was 45°C and extension temperature was 65°C. Lack of amplifiability with either the *H. nelsoni*-specific primers or the actin primers prompted design of a series of primers that would amplify small regions of the small subunit ribosomal DNA (SSU rDNA) (approximately 90 to 360 bp) of most haplosporidians. The PCR primers, designated HAP-F1, HAP-F2, HAP-R1, HAP-R2, and HAP-R3 (Table 1), encompassed the variable region targeted by the DNA probes MSX1347 and SSO1318. The HAP PCR reaction mixtures were prepared and cycled as described above, except the annealing temperature was 48°C for the HAP-F1 reactions and 44°C for the HAP-F2 reactions and the extension time was 1 min per cycle. An aliquot (10% of reaction volume) of each PCR reaction was checked for amplification product by agarose gel electrophoresis and ethidium bromide staining (see Table 2).

Sequencing. PCR product was ethanol precipitated, ligated into the plasmid vector pCR2.1 (Invitrogen),

Table 1. PCR primers. MSX-A' is MSX-A with an additional 8 bases at the 5' end; the latter primer, along with MSX-B, was reported previously (Stokes et al. 1995). MSX-A' and MSX-B are *Haplosporidium nelsoni*-specific, targeting a 565 bp region of the SSU rDNA. The HAP primers amplify small regions of the SSU rDNA of most haplosporidians. All of the HAP amplification products encompass the variable region targeted by the *H. nelsoni* and *H. costale* DNA probes

Primer name	Primer sequence (5'–3')
MSX-A'	CGACTTTGGCATTAGGTTTCAGACC
MSX-B	ATGTGTTGGTGACGCTAACCG
HAP-F1	GTTCTTTCWTGATTCTATGMA
HAP-F2	GCCRTCTAACTAGCTS
HAP-R1	CTCAWKCTTCCATCTGCTG
HAP-R2	GATGAAYAATTGCAATCAYCT
HAP-R3	AKRHRTTCCTWGTTCAAGAYGA

Table 2. Expected PCR product sizes from haplosporidian DNA with the primer pairs listed. Oyster (*Crassostrea gigas* or *C. virginica*) DNA does not yield amplification product with any of these primer pairs

Primer pair	Expected PCR product (bp)		
	<i>Haplosporidium nelsoni</i>	<i>H. costale</i>	<i>Minchinia terebinis</i>
MSX-A' + MSX-B	573	None	None
HAP-F1 + HAP-R1	186	191	185
HAP-F1 + HAP-R2	331	336	327
HAP-F1 + HAP-R3	348	353	344
HAP-F2 + HAP-R1	94	99	93
HAP-F2 + HAP-R2	239	244	235
HAP-F2 + HAP-R3	256	261	252

and transformed into *Escherichia coli* INVF' cells. Clones with inserts were cycle sequenced via simultaneous bidirectional sequencing using M13 forward and reverse primers labeled with the fluorescent dyes IRD-700 and IRD-800 (LI-COR). Sequencing reactions were electrophoresed on a 41 cm 5% polyacrylamide gel in a Li-Cor Model 4200 automated sequencer. Sequence data were aligned with haplosporidian SSU rDNA sequences using the MacVector software package (Oxford Molecular).

RESULTS

Pathology

Adult oysters appeared gravid or in different stages of gonad resorption during the sampling period. Histological examination of stained sections showed the presence of haplosporidian-like infections within the digestive gland and gill connective tissues of juvenile oysters. Among the 791 individuals examined, 2 were found infected (prevalence 0.27%): a 7 mo old spat from Arcachon Bay (south French Atlantic coast—July 1993) and a 14 mo old individual collected in Morlaix area (Brittany—August 1993). This oyster had been transferred to Brittany from Arcachon Bay. The protozoan infection was accompanied by infiltration of host hemocytes into the areas of parasitic infection. Numerous early plasmodial stages (2 to 8 nuclei), 8 to 15 μm in diameter, were found in connective tissues of gills and digestive gland (Fig. 1). No sporogonic stages or spores were observed. The normal architecture of affected tissues was altered; necrosis and cell lysis were observed within host tissues surrounding parasites.

Electron microscopy

Electron microscopic examination showed uni- and multinucleated plasmodia, 8 to 15 μm in diameter,

scattered in connective tissues of gills and digestive gland (Fig. 2). Uninucleated and binucleated forms were the most frequently seen (Figs. 3 & 4), multinucleated plasmodia (more than 2 nuclei) were rarely observed (Fig. 5). Parasitic cells at this development stage were not delimited by a wall. The fine structure of plasmodia in affected tissues was diverse; however, most plasmodial stages possessed osmophilic round bodies 150 to 180 nm in diameter scattered throughout the cytoplasm

(Figs. 2, 4 & 5). These structures were limited by a membrane and identified by an inner electron-lucent configuration usually having appearance of a 'squat vase' (Fig. 6). The area within this configuration was usually not as electron-dense as the area to its exterior. The haplosporidian electron-dense bodies or haplosporosomes were physically associated with membrane-limited regions and numerous membrane 'spherules'. The round dense bodies appeared to bud off from these areas (Fig. 7). The number of haplosporosomes within any given plasmodium varied greatly, but these structures were often abundant (average 51 ± 19 , $n = 20$, per plasmodium section). An additional structure consistently found in the plasmodium cytoplasm was round, approximately 130 nm in diameter, membrane-limited, and had a dense core which appeared to be connected to the periphery by fine radiating fibers arranged in a spike-like fashion (Fig. 8). The cytoplasmic fine structure included large distended oval or round mitochondria with vesicular cristae (Figs. 3, 4 & 5). Endoplasmic reticulum was sparse and free of ribosomes, the latter being found in high density in the

ground cytoplasm. The nuclei were usually paired and each was characterized by a single prominent endosome which was round or oval and against the nuclear envelope (Figs. 4 & 5). The nuclear Feulgen and Rossenbeck reaction indicated primarily peripheral location of the DNA. Degenerating parasites were occasionally found with pycnotic nuclei, swollen mitochondria and leached plasma membranes (Fig. 9).

DNA-based assays

In situ hybridization of DNA probe MSX1347 (*Haplosporidium nelsoni*) to infected oyster tissue sections yielded strong hybridization of the probe to plasmodia, while DNA probe SSO1318 (*H. costale*) did not

hybridize (Fig. 10). Both probes hybridized with the plasmodia in the respective positive controls (data not shown). Repeated attempts to amplify DNA isolated from tissue sections were unsuccessful using the 'universal' actin primers and the *H. nelsoni*-specific primers, MSX-A' and MSX-B. Consequently, the HAP primers were developed to specifically amplify smaller regions of haplosporidian SSU rDNA from infected host tissue DNA. All 6 HAP primer pair combinations were used in PCR amplifications of the Morlaix oyster tissue DNA; only HAP-F2 + HAP-R1 yielded PCR product, which was the size expected for a haplosporidian (Table 2). Eight clones of the PCR product were sequenced. The sequence was 94 bases long and was identical to the published sequence for bases 1305 to 1398 of the *H. nelsoni* SSU rDNA.

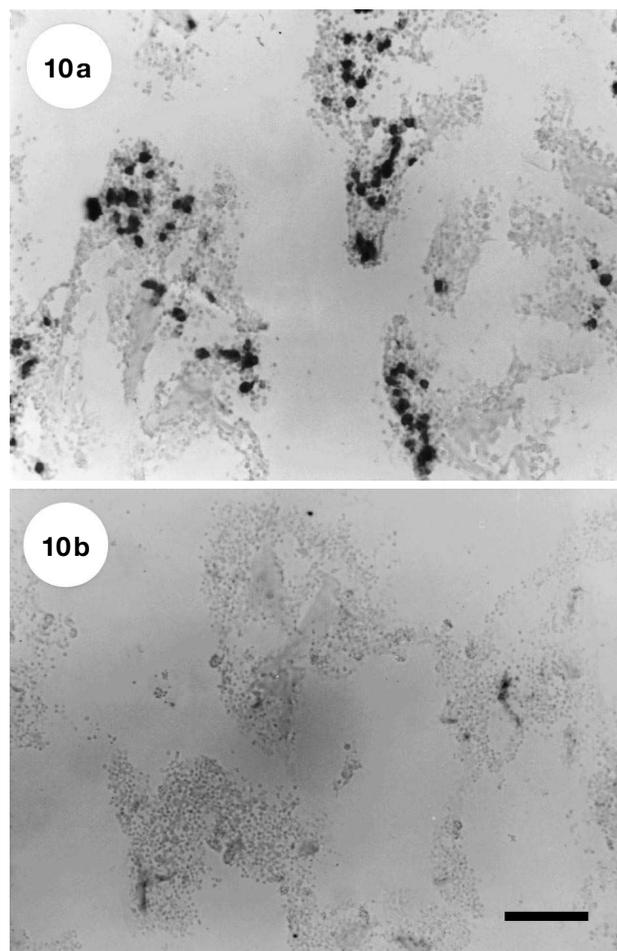

Fig. 10. *In situ* hybridizations with DNA probes on adjacent tissue sections of haplosporidian-infected *Crassostrea gigas* collected in Morlaix. Scale bar = 100 μ m. (a) Positive reaction with plasmodia using 5 ng μ l⁻¹ of *Haplosporidium nelsoni*-specific probe MSX1347. (b) Absence of reaction with plasmodia using 5 ng μ l⁻¹ of *H. costale*-specific probe SSO1318

DISCUSSION

The haplosporidian parasite observed in *Crassostrea gigas* from the French Atlantic coast is similar to *Haplosporidium nelsoni* of *C. virginica* in tissue location, morphology and size of plasmodial stages. Infection with the haplosporidian parasite is characterized by the presence of uni- and multinucleated plasmodia throughout gill, gonad and digestive gland connective tissues. Parasites elicit a hemic response. These observations are consistent with early systemic infections of *H. nelsoni* (Andrews 1966, Perkins 1968, 1969). The dense bodies reported here are typical of those observed in the cytoplasm of *H. nelsoni* plasmodial stages (Scro & Ford 1990), in contrast with the round, oval or pyriform haplosporosomes of *H. costale* (Perkins 1969). In addition to difference in shape, the electron-dense bodies of *H. costale* were found less abundantly than those in *H. nelsoni*. Such differences were used to help distinguish the plasmodia of both species; for example, a section through a *H. nelsoni* plasmodium often showed more than 70 free electron-dense bodies, whereas in a comparable sized plasmodial section of *H. costale* a maximum of 15 structures were counted (Perkins 1968, 1969). The average number of haplosporosomes counted here (51) is more comparable to the number 70, previously observed in *H. nelsoni* plasmodia, than to the 15 observed in *H. costale* plasmodia (Perkins 1968, 1969). The amount of haplosporosomes within plasmodia in *C. gigas*, however, varied greatly per parasite section (Perkins 1968, 1969). The additional structures seen in the cytoplasm of *C. gigas* haplosporidian parasites are similar to the 'concentric bodies' described by Scro & Ford (1990) in the *H. nelsoni* cytoplasm.

Results of the DNA-based diagnostic assays supported each other. Plasmodia in the Morlaix *Crassostrea gigas* sample hybridized only with the *Haplosporidium nelsoni*-specific DNA probe MSX1347 and the sequence of the PCR-amplified DNA was identical to the corresponding SSU rDNA sequence of *H. nelsoni*. Even though DNA isolated from tissue sections of the oyster collected from Morlaix was not amplifiable with the primer pairs MSX-A' + MSX-B or actin 480 + 483, it did yield amplification product with the haplosporidian SSU rDNA primers HAP-F2 + HAP-R1. This is consistent with observations that PCR amplification of target regions greater than 200 to 500 bp is very difficult to achieve on DNA from archival samples, due to fragmentation of DNA and crosslinking of histones to DNA during formaldehyde fixation of tissues (Pääbo 1990, Hamazaki et al. 1993, Vachot & Monnerot 1996).

DNA-based diagnostics have been used previously (Burreson et al. 2000) to identify haplosporidian plas-

modia that were detected in *Crassostrea gigas* from Korea (Kern 1976) and Japan and California, USA (Friedman 1996). Lack of sporogonic stages in the latter survey precluded definite identification of the haplosporidian. Therefore, *in situ* hybridizations using MSX1347, the same DNA probe used in this study, were performed on paraffin-embedded tissue sections of the infected oysters from Japan and California, and one of the non-sporulating oysters from Korea. The *Haplosporidium nelsoni* probe hybridized with haplosporidian plasmodia in all of these oysters (Burreson et al. 2000). In addition, genomic DNA was isolated from the infected California oysters and subjected to PCR amplification with the primers MSX-A and MSX-B (Stokes et al. 1995). DNA from the California oysters amplified with the *H. nelsoni* PCR primers and the 565 bp sequence was identical to the *H. nelsoni* SSU rDNA target region, with only one nucleotide difference (Burreson et al. 2000). In this study, the *H. nelsoni* primers MSX-A' (same as MSX-A, but with an additional 8 bases at the 5' end) and MSX-B did not amplify the plasmodial DNA but the haplosporidian primers HAP-F2 and HAP-R1 did. Even though the PCR product generated by the HAP primers was shorter, it amplified a variable region of the SSU rDNA that contains sequence unique to each haplosporidian.

Tissues from the California oysters were fixed for only 24 h in neutral buffered formalin (Burreson et al. 2000), whereas tissues from the French oysters in this study were fixed for at least 1 wk in Davidson's AFA. The former fixation treatment has been shown to yield DNA that can PCR amplify longer target regions than DNA from long-term storage in unbuffered fixative (Vachot & Monnerot 1996). Davidson's AFA is the fixative of choice for marine invertebrates. Traditional fixation procedures include tissue storage in Davidson's AFA from 1 d up to a few months. Diagnosis of parasites by histological examination is not affected by this practice; however, the quality of DNA isolated from fixed tissues is reduced the longer those tissues are stored in fixative (Hamazaki et al. 1993, O'Leary et al. 1994). The HAP primers were developed in order to work with archived samples that were fixed for indeterminate periods. The smaller target regions are more amenable to PCR amplification and the primers specifically amplify most haplosporidians from the total genomic DNA isolated from infected hosts.

The morphological observations, *in situ* hybridization with the *Haplosporidium nelsoni*-specific probe, and sequence of the PCR amplified product that was identical to an SSU rDNA variable region of *H. nelsoni* confirm that the haplosporidian parasite in *Crassostrea gigas* from the French Atlantic coast is *H. nelsoni* or a

very closely related parasite. Indeed, the molecular methods used can only confirm identification in relation to known species or strains. Other parasites for which sequence data are not available could conceivably give the same identification.

The prevalence of infected oysters found in this study was very low (0.27%). The 2 infected oysters originated from the same area (Arcachon Bay, south Atlantic French coast). Other disease survey studies of *Crassostrea gigas* have found similarly low prevalences of haplosporidian infection. During a 4 yr sampling of 1438 oysters from Korea, 4 (0.28%) were infected with haplosporidians (Kern 1976). In a survey of *C. gigas* from Japan, 10/100 spat and 1/171 adult oysters were infected with haplosporidians that closely resembled *Haplosporidium nelsoni* (Friedman et al. 1991). In a subsequent study, Friedman (1996) observed haplosporidian infections in 1 to 3% of oysters from Japan and up to 7% of oysters from California. In 2 yr of routine surveys of *C. gigas* from Etang de Thau, France, Comps & Pichot (1991) found 3 oysters infected with haplosporidians. Based on electron microscopic studies of the spores, the parasite seemed similar to *H. costale*. The low prevalence of haplosporidian parasite infections in *C. gigas* suggests that this oyster species is less sensitive to the infection than *C. virginica* and that *C. gigas* can react against the parasite and limit its spread. Moreover, early plasmodial stages are mainly observed in infected *C. gigas* oysters, suggesting that the parasite is not able to develop normally in this bivalve species.
